### Abstract
In this paper, we propose a simple methodology for investigating how shocks to trend and cycle are correlated in unidentified unobserved components models, in which the correlation is not identified. The proposed methodology is applied to U.S. and U.K. real GDP data. We find that the correlation parameters are negative for both countries. We also investigate how changing the identification restriction results in different trend and cycle estimates.

1. INTRODUCTION

In business cycle analysis, it is often supposed that real GDP consists of two unobserved components (UC): a permanent and a transitory component. Shocks to the permanent component have long-lasting effects, whereas shocks to the transitory component are temporary and vanish in the long run. We refer to these two components as “trend” and “cycle”, respectively. Estimating these two components has been an important issue in business cycle analysis. The UC model is one of the most commonly used models for this purpose (see, for example, Watson (1986), Clark (1987), Basistha (2007), Basistha and Nelson (2007), Oh, Zivot, and Creal (2008), Sinclair (2009) and references therein for applications of UC models).

In this model, the trend is assumed to be a random walk process and the cycle is assumed to be a stationary process. It is conventional to assume that shocks to the trend and cycle are uncorrelated for the identification of model parameters although this assumption is unreasonable, as argued by Clark (1987, pp. 800–801) and Zarnowitz.
and Ozyildirim (2006). Morley, Nelson, and Zivot (2003) (2003, henceforth MNZ) estimate a UC model with a stationary AR(2) cycle process, for U.S. quarterly real GDP. They show that one can identify and estimate the correlation parameter under this specification of cycle. Their estimate of the correlation parameter of $-0.9062$ is significantly different from zero according to their likelihood ratio test. They show also that the trend and cycle estimates with and without the zero correlation restriction are very different.

The main objective of this paper is to reinvestigate how shocks to these two components are correlated by applying unidentified UC models, in which a correlation is not identified unless we impose an identification restriction. We investigate how different identification restrictions lead to different values of the correlation between the two shocks. We also demonstrate how changing identification restriction results in different trend and cycle estimates. The empirical analysis in Section 4 shows that the trend and cycle estimates with different identification restrictions can be substantially different.

We call a UC model with ARMA($p$, $q$) cycle a UC-ARMA($p$, $q$) model. In explaining our methodology in Sections 2 and 3, we mainly consider a UC–ARMA(2, 1) model, for ease of exposition. The proposed methodology can, in principle, be extended to UC models with higher order ARMA cycles although the related calculations become more involved. In Section 2, first, we show that the UC–ARMA(2, 1) model is observationally equivalent to MNZ’s UC–AR(2) model in the sense that these two UC models have the same autocovariance structure. A difficulty in applying the UC–ARMA(2, 1) model is that, unlike the UC–AR(2) model, it has a correlation parameter that cannot be identified (and hence estimated) unless we impose an identification restriction. Next, however, we show that for the correlation parameter, there is an upper bound implied by an unrestricted ARIMA(2, 1, 2) model, which is an observationally equivalent alternative representation of the UC–ARMA(2, 1) model. We propose a simple methodology for finding the implied upper bound. The basic idea of the methodology is to examine how the value of the correlation implied by an unrestricted ARIMA model changes when we impose different identification restrictions. In this way, we can obtain an implicit relationship between the identification restrictions and the resulting values of the correlation. See Section 3 for more details.

The proposed methodology is applied to U.S. and U.K. real GDP data. For both countries, it is found that the upper bounds of the correlations are negative. This implies that the two shocks are negatively correlated. We use UC-ARMA(2, 1) models, estimated under different identification restrictions, to estimate the trend and cycle. We find that estimates of the trend and cycle can vary substantially depending on the identification restrictions imposed. We also find that setting the MA(1) parameter equal to $0.9062$ is significantly different from zero according to their likelihood ratio test. They show also that the trend and cycle estimates with and without the zero correlation restriction are very different.

We call a UC model with ARMA($p$, $q$) cycle a UC-ARMA($p$, $q$) model. In explaining our methodology in Sections 2 and 3, we mainly consider a UC–ARMA(2, 1) model, for ease of exposition. The proposed methodology can, in principle, be extended to UC models with higher order ARMA cycles although the related calculations become more involved. In Section 2, first, we show that the UC–ARMA(2, 1) model is observationally equivalent to MNZ’s UC–AR(2) model in the sense that these two UC models have the same autocovariance structure. A difficulty in applying the UC–ARMA(2, 1) model is that, unlike the UC–AR(2) model, it has a correlation parameter that cannot be identified (and hence estimated) unless we impose an identification restriction. Next, however, we show that for the correlation parameter, there is an upper bound implied by an unrestricted ARIMA(2, 1, 2) model, which is an observationally equivalent alternative representation of the UC–ARMA(2, 1) model. We propose a simple methodology for finding the implied upper bound. The basic idea of the methodology is to examine how the value of the correlation implied by an unrestricted ARIMA model changes when we impose different identification restrictions. In this way, we can obtain an implicit relationship between the identification restrictions and the resulting values of the correlation. See Section 3 for more details.

The proposed methodology is applied to U.S. and U.K. real GDP data. For both countries, it is found that the upper bounds of the correlations are negative. This implies that the two shocks are negatively correlated. We use UC-ARMA(2, 1) models, estimated under different identification restrictions, to estimate the trend and cycle. We find that estimates of the trend and cycle can vary substantially depending on the identification restrictions imposed. We also find that setting the MA(1) parameter equal to $0.9062$ is significantly different from zero according to their likelihood ratio test. They show also that the trend and cycle estimates with and without the zero correlation restriction are very different.

We call a UC model with ARMA($p$, $q$) cycle a UC-ARMA($p$, $q$) model. In explaining our methodology in Sections 2 and 3, we mainly consider a UC–ARMA(2, 1) model, for ease of exposition. The proposed methodology can, in principle, be extended to UC models with higher order ARMA cycles although the related calculations become more involved. In Section 2, first, we show that the UC–ARMA(2, 1) model is observationally equivalent to MNZ’s UC–AR(2) model in the sense that these two UC models have the same autocovariance structure. A difficulty in applying the UC–ARMA(2, 1) model is that, unlike the UC–AR(2) model, it has a correlation parameter that cannot be identified (and hence estimated) unless we impose an identification restriction. Next, however, we show that for the correlation parameter, there is an upper bound implied by an unrestricted ARIMA(2, 1, 2) model, which is an observationally equivalent alternative representation of the UC–ARMA(2, 1) model. We propose a simple methodology for finding the implied upper bound. The basic idea of the methodology is to examine how the value of the correlation implied by an unrestricted ARIMA model changes when we impose different identification restrictions. In this way, we can obtain an implicit relationship between the identification restrictions and the resulting values of the correlation. See Section 3 for more details.

The proposed methodology is applied to U.S. and U.K. real GDP data. For both countries, it is found that the upper bounds of the correlations are negative. This implies that the two shocks are negatively correlated. We use UC-ARMA(2, 1) models, estimated under different identification restrictions, to estimate the trend and cycle. We find that estimates of the trend and cycle can vary substantially depending on the identification restrictions imposed. We also find that setting the MA(1) parameter equal to $0.9062$ is significantly different from zero according to their likelihood ratio test. They show also that the trend and cycle estimates with and without the zero correlation restriction are very different.

We call a UC model with ARMA($p$, $q$) cycle a UC-ARMA($p$, $q$) model. In explaining our methodology in Sections 2 and 3, we mainly consider a UC–ARMA(2, 1) model, for ease of exposition. The proposed methodology can, in principle, be extended to UC models with higher order ARMA cycles although the related calculations become more involved. In Section 2, first, we show that the UC–ARMA(2, 1) model is observationally equivalent to MNZ’s UC–AR(2) model in the sense that these two UC models have the same autocovariance structure. A difficulty in applying the UC–ARMA(2, 1) model is that, unlike the UC–AR(2) model, it has a correlation parameter that cannot be identified (and hence estimated) unless we impose an identification restriction. Next, however, we show that for the correlation parameter, there is an upper bound implied by an unrestricted ARIMA(2, 1, 2) model, which is an observationally equivalent alternative representation of the UC–ARMA(2, 1) model. We propose a simple methodology for finding the implied upper bound. The basic idea of the methodology is to examine how the value of the correlation implied by an unrestricted ARIMA model changes when we impose different identification restrictions. In this way, we can obtain an implicit relationship between the identification restrictions and the resulting values of the correlation. See Section 3 for more details.

The proposed methodology is applied to U.S. and U.K. real GDP data. For both countries, it is found that the upper bounds of the correlations are negative. This implies that the two shocks are negatively correlated. We use UC-ARMA(2, 1) models, estimated under different identification restrictions, to estimate the trend and cycle. We find that estimates of the trend and cycle can vary substantially depending on the identification restrictions imposed. We also find that setting the MA(1) parameter equal to $0.9062$ is significantly different from zero according to their likelihood ratio test. NAGAKURA: HOW ARE SHOCKS TO TREND AND CYCLE CORRELATED? 3

zero, or specifying the cycle as an AR(2) process, which has been one of the most commonly used specification for the cycle in the UC model literature, is not supported by the data on U.K. real GDP.

Our empirical analysis suggests that it is important to impose an appropriate identification restriction for properly estimating the trend and cycle. We discuss also on what is an appropriate identification restriction. In fact, it is confirmed empirically that the trend (and cycle) estimates obtained under (different but) appropriate identification restrictions are identical.

The identification problem we deal in this paper is conceptually different from the identification problem known as a weak identification problem. Andrews and Cheng (2012) considered a model in which some parameters are not identified in the sense that a criterion function does not depend on those parameters if another parameters, that we call identifying parameters, take certain points, that we call non-identification points. Andrews and Cheng (2012) call a model weakly identified when the identifying parameters are close to the non-identification points. On the other hand, the some parameters of the model we consider in this paper are not identified in the sense that there are infinitely many sets of parameters that result in the same autocovariance functions, regardless of the values of other parameters. See Andrews and Cheng (2012) and references therein for other sorts of identification problems.

The rest of the paper is organized as follows. In the next section, we briefly overview the identification problem of UC models. In Section 3, we propose a simple methodology to find an upper bound of the correlation for unidentified UC models. In Section 4, we apply the proposed methodology to U.S. and U.K. real GDP data. The final section provides a summary and concluding remarks.

2. OVERVIEW OF THE IDENTIFICATION PROBLEM OF UC MODELS

Let \( \{y_t\}_{t=0}^{T} \) be an observed time series, such as the log of real GDP. We suppose that \( y_t \) is the sum of two unobserved stochastic processes, a random walk process \( \tau_t \) and a stationary finite order ARMA\((p, q)\) process \( c_t \); these processes are conventionally termed “trend” and “cycle”, respectively, in the literature on business cycle analysis. The model is known as a UC model (hereafter, a UC-ARMA\((p, q)\) model). Formally, the model is defined as follows:

\[
\begin{align*}
y_t &= \tau_t + c_t, \\
\tau_t &= \mu + \tau_{t-1} + \eta_t, \\
\phi(L)c_t &= \theta(L)\varepsilon_t, \\
\eta_t &\sim i.i.d.(0, \sigma^2_{\eta}), \\
\varepsilon_t &\sim i.i.d.(0, \sigma^2_{\varepsilon}), \\
\text{cov}(\eta_t, \varepsilon_{t+s}) &= \begin{cases} \sigma_{\eta\varepsilon} & \text{for } s = 0, \\ 0 & \text{otherwise}, \end{cases}
\end{align*}
\] (1)

where \( \phi(L) = 1 - \phi_1L - \cdots - \phi_pL^p \) and \( \theta(L) = 1 + \theta_1L + \cdots + \theta_qL^q \) are \( p \)th order AR and \( q \)th order MA polynomials, respectively, that satisfy the stationarity and invertibility conditions; that is, the modulus of the roots of \( \phi(z) = 0 \) and \( \theta(z) = 0 \) are all outside the unit circle.

From (1), we have
\[ \phi(L)(1 - L)\gamma_t = \phi(1)\mu + \phi(L)\eta_t + (1 - L)\theta(L)\varepsilon_t. \]  
(2)

The right-hand side of (2) is the sum of two MA processes whose innovations are correlated. However, it can be shown that this part can be expressed by an MA\((q^*)\) process with a single innovation \(u_t\), where \(q^* = \max\{p, q + 1\}\) (see, for example, Granger and Morris, 1976). This implies that \(y_t\) can alternatively be represented as an ARIMA\((p, q^*)\) process, as follows:

\[ \phi(L)(1 - L)y_t = \mu^* + \theta^*(L)\varepsilon_t, \quad u_t \sim i.i.d. (0, \sigma_u^2), \]
(3)

where \(\mu^* \equiv \phi(1)\mu\), and \(\theta^*(L) \equiv 1 + \theta_1^*L + \cdots + \theta_q^*L^q\). Note that the AR coefficients in (2) and (3) are the same. This representation of the UC–ARMA\((p, q)\) model is commonly referred to as the ARIMA \((p, 1, q)\) reduced form.

MNZ point out that if one sets \(p = 2\) and \(q = 0\), then the parameters of the resulting UC–AR(2) model are uniquely identified from its ARIMA\((2, 1, 2)\) reduced form parameters. To see this, let \(\gamma_j\) denote the \(j\)th order autocovariance of the MA part of (3).

The first three autocovariances, \(\gamma_0, \gamma_1, \text{ and } \gamma_2\), in terms of the ARIMA\((2, 1, 2)\) reduced form parameters, are given by

\[ \gamma_0 = \sigma_\mu^2 + 2\sigma_\varepsilon^2, \quad \gamma_1 = \sigma_\mu^2 + \sigma_\varepsilon^2 + (1 - \theta_1 - \theta_2)\sigma_\eta^2, \quad \gamma_2 = \sigma_\mu^2 + \sigma_\varepsilon^2 + (1 - \theta_1 - \theta_2)\sigma_\varepsilon^2. \]

(4)

(See MNZ for a detailed derivation of the equations in (4)). Thus, given the ARIMA\((2, 1, 2)\) reduced form parameters, which include \(\phi_1, \phi_2, \theta_1, \text{ and } \theta_2\), we can solve the three equations in (4) for the three unknown UC model parameters, \(\sigma_\mu^2, \sigma_\varepsilon^2, \text{ and } \sigma_\eta^2\), uniquely. The correlation \(\rho\) is calculated as \(\rho = \sigma_\eta^2/(\sigma_\varepsilon^2\sigma_\eta^2)\).

A problem occurs when \(p = 2\) and \(q = 1\); then \(y_t\) follows a UC–ARMA\((2, 1)\) process, and there is one additional parameter, namely, \(\theta_1\), the MA\((1)\) coefficient of the ARMA\((2, 1)\) cycle process. Although it is easy to show that its reduced form is also an ARIMA\((2, 1, 2)\) process, the four UC model parameters, \(\sigma_\mu^2, \sigma_\varepsilon^2, \sigma_\eta^2, \text{ and } \theta_1\) cannot be uniquely identified from its ARIMA\((2, 1, 2)\) reduced form parameters. To show this, we compare the autocovariances of the MA parts of the models. In terms of the UC model parameters, the autocovariances \(\gamma_j, j = 0, 1, 2\) are:

\[ \gamma_0 = \sigma_\mu^2 + \sigma_\varepsilon^2 + (1 - \theta_1 - \theta_2)\sigma_\eta^2, \quad \gamma_1 = \sigma_\mu^2 + \sigma_\varepsilon^2 + 2(1 - \theta_1 - \theta_2)\sigma_\eta^2, \quad \gamma_2 = \sigma_\mu^2 + \sigma_\varepsilon^2 + 2(1 - \theta_1 - \theta_2)\sigma_\eta^2. \]

(5)

3 The sum of two MA processes with correlated innovations can be expressed as the sum of two MA processes with uncorrelated innovations. Let \(\theta_1(L)\varepsilon_i, t = 1, 2\) be two MA processes with \(\varepsilon_i, t \sim i.i.d. (0, \sigma_i^2)\) and

\[ \text{cov}(\varepsilon_1, t, \varepsilon_2, t) = \sigma. \]

Define \(\tilde{\varepsilon}_i \equiv \varepsilon_1, t - (\sigma/\sigma_1^2)\varepsilon_1, t\). Then, \(\text{cov}(\varepsilon_1, t, \tilde{\varepsilon}_i) = 0\) and \(\sum_{t=1}^2 \theta_1(L)\varepsilon_i, t = \tilde{\theta}(L)\varepsilon_1, t + \tilde{\theta}_2(L)\varepsilon_1, t\), where \(\tilde{\theta}(L) = \theta_1(L) + (\sigma/\sigma_1^2)\theta_2(L)\).
where $\theta_1$ is the MA (1) coefficient of the ARMA(2, 1) cycle process.

Note that there are only three equations for the four unknown UC model parameters, $\sigma_n^2$, $\sigma_{\eta\epsilon}$, $\sigma_\gamma^2$ and $\theta_1$. Thus, the equations in (5) cannot be uniquely solved for these four UC model parameters. To solve these equations, we must impose a restriction, which we term an “identification restriction”, on $\theta_1$. For example, setting $\theta_1 = 0$ reduces the model to a UC–AR(2) model. This restriction is not testable because under the alternative hypothesis the model parameters are not identified. In general, the order condition for identification of the UC–ARMA($p$, $q$) model is satisfied when $p \geq q + 2$. The model parameters are just identified when this equality holds. Thus, although UC-ARMA($p$, $p-2$) and UC-ARMA($p$, $p-1$) models both have an ARIMA($p$, $p$) reduced form, the former model is identified while the latter model is not identified.

MNZ apply a UC–AR(2) model to U. S. quarterly real GDP data and find that the estimated correlation $\rho$ is significantly negative. However, the point of our paper is that the true data generating process may be the UC–ARMA(2, 1) model that is observationally equivalent to the UC–AR(2) model. In that case, one cannot identify $\rho$.

3. METHODOLOGY

In this section, we illustrate a simple method for finding an upper bound for the correlation given the unrestricted ARIMA model parameters. The basic idea is to examine how the value of the correlation implied by an unrestricted ARIMA model changes when we impose different identification restrictions.

Lengthy calculations can be used to solve the equations in (5) to obtain the following expressions for the three UC model parameters (we briefly argue how to derive the solutions in Appendix A):

\[
\begin{align*}
\sigma_n^2 &= \frac{\gamma_0 + 2\gamma_1 + 2\gamma_2}{(1 - \phi_1 - \phi_2)^2}, \\
\sigma_\epsilon^2 &= \frac{-2(1 - \phi_1\theta_1 + \phi_1 + \phi_2\theta_1)(\gamma_2 + \phi_2\sigma_n^2)}{2\theta_1(1 - \phi_1\theta_1 + \phi_1 + \phi_2\theta_1) - 2(\theta_1 + \phi_2)(1 - \theta_1 + \theta_1^2)}, \\
\sigma_{\eta\epsilon} &= \frac{\theta_1[\gamma_0 - (1 + \phi_1^2 + \phi_2^2)\sigma_n^2 + 2(1 - \theta_1 + \theta_1^2)(\gamma_2 + \phi_2\sigma_n^2)]}{2\theta_1(1 - \phi_1\theta_1 + \phi_1 + \phi_2\theta_1) - 2(\theta_1 + \phi_2)(1 - \theta_1 + \theta_1^2)}.
\end{align*}
\]

Note that the variance of the trend shock, $\sigma_n^2$, is identified and is equivalent to the long-run variance of the first differences of $\{y_t\}$. This result holds in general: for any UC–ARMA($p$, $q$) model, the variance of the trend shock is always identified as the long-run variance of the first differences; that is, $\sigma_n^2 = \psi(1)^2\sigma_n^2$, where $\psi(1) = \theta^*(1)/\phi(1)$. This was first pointed out by Cochrane (1988, p. 908).

Note that given the ARIMA(2, 1, 2) reduced form parameters, the three UC model parameters above are functions of $\theta_1$. Hence, given $\theta_1$, these functions determine the values of the three UC model parameters that satisfy the equations in (5), from which we can calculate $\rho$. In this way, we can obtain an implicit relationship between the “identification restrictions” imposed on $\theta_1$ and the resulting values of the correlation $\rho$. Figure 2(a) plots such pairs of values for $\theta_1$ and $\rho$, given estimates of the ARIMA(2,

Note: The following ARIMA(2, 1, 2) model was estimated by the exact maximum likelihood estimation:

$$\phi(L)(\Delta y - \mu) = \theta(L)u_t, \quad u_t \sim NID(0, \sigma^2_u),$$

where $\phi(L) = 1 - \phi_1 L - \phi_2 L^2$, and $\theta^*(L) = 1 + \theta^*_1 L + \theta^*_2 L^2$. Standard errors are in parentheses. The rows with $\sigma^2_{lrv}$, $\sigma^2_{ucv}$, and $\psi(1)$ display estimates of the long-run variance, the unconditional variance and the (cumulated) impulse response measure, namely, $\psi(1) = \theta^*(1)/\phi(1)$, respectively. The last row reports the log-likelihood.

1. 2) model for U.S. quarterly real GDP, which are reported in the second column of Table 1.

The implied values of the correlations are all negative, and the upper bound of the correlation is around $-0.75$. The dashed line shows that if we restrict $\theta_1$ to be 0, in which case the UC–ARMA(2, 1) model reduces to the UC–AR(2) model, then the resulting implied correlation is around $-0.95$, which is lower than the estimate obtained by MNZ. This is because our data are different from theirs; in particular, our data cover a longer sample period (more details on the data set are given in the next section). Note that there are ranges of values for $\theta_1$ that imply correlations of less than $-1$, which thus violate the condition for positive definiteness of the covariance matrix. This means that
UC–ARMA(2, 1) models with values of $\theta_1$ in such ranges are inconsistent with the estimated unrestricted ARIMA(2, 1, 2) model. We refer to such values of $\theta_1$ as “improper identification restrictions”; values of $\theta_1$ at which $|\rho| \leq 1$ constitute “proper identification restrictions”. In the figure, we display values of $\rho$ based only on values of $\theta_1$ in a particular range; this is because we confirmed that values for $\theta_1$ outside of the range are inconsistent with $|\rho| \leq 1$.

In this way, we can find an upper bound for the correlation parameter. The methodology can be easily extended for other unidentified UC models.

4. EMPIRICAL APPLICATIONS

In this section, we apply the proposed methodology to U.S. and U.K. quarterly real GDP data. These quarterly real GDP data cover the period from 1946:4 to 2006:3 (yielding 238 observations) for the U.S. and the period from 1955:4 to 2006:2 (yielding 202 observations) for the U.K. For these periods, Figure 1 shows the percentage growth rates in GDP.

Table 1 reports the estimates of the unrestricted ARIMA (2, 1, 2) model for each (logged) GDP series. Figure 2 graphs the implied relationships between $\theta_1$ and $\rho$ for these GDP data, obtained by using the methodology described in the previous section. The implied values of the correlations are all negative for both countries. The upper bound for the correlation differs between the two countries; it is about $-0.75$ for U.S. and $-0.993$ for U.K. This implies that the two shocks are highly negatively correlated. Note that because these values are upper bounds, the actual correlations may be lower than these values. For the U.K. GDP data, the range of $\theta_1$ values that satisfies the condition for positive definiteness of the covariance matrix (i.e., $|\rho| \leq 1$) does not include $\theta_1 = 0$. This implies that, for the U.K., the restriction that $\theta_1 = 0$, under which the model reduces to the UC–AR(2) model, is inconsistent with the estimated unrestricted ARIMA models. In other words, the U.K. real GDP data do not support the UC–AR(2) specification.

The results show that for both countries, in particular U.K., the correlations of two shocks are highly negative. One hypothesis for explaining these strong negative correlations is that although we assumed that the real GDP is driven by two different shocks, namely, trend and cycle shocks, the real GDP is actually driven by only one shock that affects oppositely to trend and cycle. Another possible hypothesis is that the trend is not a random walk process. As shown in Nagakura (2008) and Nagakura and Zivot (2007), if the trend is not a random walk process but follows a certain class of I(1) process, then estimates of the correlation in the UC model in that the trend is assumed to be a random walk process tends to be negative. See Nagakura (2008) and Nagakura and Zivot (2007) for more details.

If we set the value of $\theta_1$ a priori to, for example, $\theta_1 = 0$, we can directly estimate
the other three UC model parameters from a state space representation. However, the above result suggests that we should not arbitrarily choose the value of $\theta_1$. One would expect UC models estimated under different identification restrictions, particularly improper identification restrictions, to produce different trend and cycle estimates. To address this concern, we estimate the UC–ARMA(2, 1) model directly under different identification restrictions, including proper and improper restrictions, and then estimate the cycle and trend from these estimated UC models. In the estimation of UC models, we impose the positive definiteness condition on the covariance matrix parameters and impose the stationarity conditions on the AR(2) coefficients.

Table 2 reports the estimation results for the UC–ARMA(2, 1) model. The values of $\theta_1$ in the first row are the restrictions imposed in advance. The asterisks denote improper restrictions. When we impose proper restrictions, the values of the log-likelihoods are

\[4\] From footnote 4, it is obvious that if $\theta_1$ is fixed, $\gamma_0$, $\gamma_1$, and $\gamma_2$ are uniquely determined from $\sigma_\eta^2$, $\sigma_\varepsilon^2$, and $\sigma_{\eta\varepsilon}$, which implies that if $\theta_1$ is fixed, we can estimate $\sigma_\eta^2$, $\sigma_\varepsilon^2$, and $\sigma_{\eta\varepsilon}$ by the MLE under Gaussian assumption for $\varepsilon_t$ and $\eta_t$. 

Figure 1. Growth rates of U.S. and U.K. real GDP
the same as those of the unrestricted ARIMA model and are higher than those obtained under improper restrictions. Figures 3 and 4 display the cycle estimates for U.S. and U.K. real GDP, respectively. These are estimated by using Kalman filtering on the state space representation of the UC–ARMA(2, 1) model with estimated UC model parameters. For the U.S., Figures 3(a), (b) and (c) illustrate the cycle estimates from the UC models estimated under the restrictions $\theta_1 = 0$, $\theta_1 = -0.5$ and $\theta_1 = 0.5$, respectively. The restrictions, $\theta_1 = 0$ and $\theta_1 = -0.5$, are consistent with the estimated unrestricted ARIMA(2, 1, 2) model, whereas the restriction $\theta_1 = 0.5$ is not. The cycle estimates based on $\theta_1 = 0$ and $\theta_1 = -0.5$ are identical; however, the cycle estimates based on $\theta_1 = 0.5$ are substantially different from the other two. From Figure 4, findings for U.K. GDP are similar. Figures 4(a) and (b) illustrate the cycle estimates under proper identification restrictions and Figures 4(c) and (d) present the cycle estimates based on improper restrictions.

The cycle estimates in (a) and (b) are identical. Although it is difficult to see visually, the cycle estimates in (c) differ from those in (a) and (b).

Note: The following UC–ARMA(2, 1) model was estimated by the exact maximum likelihood estimation:
\[ y_t = \tau_t + c_t, \quad \tau_t = \mu + \tau_{t-1} + \eta_t, \quad \phi(L)c_t = \theta(L)e_t \]
\[ \eta_t \sim i.i.d. N(0, \sigma^2_\eta), \quad e_t \sim i.i.d. N(0, \sigma^2_\epsilon), \quad corr(\eta_t, e_{t+k}) = \begin{cases} \rho \sigma_\eta \sigma_\epsilon & \text{for } k = 0, \\ 0 & \text{otherwise,} \end{cases} \]

where \( \phi(L) = 1 - \phi_1 L - \phi_2 L^2 \), and \( \theta(L) = 1 + \theta_1 L \). The value of \( \theta_1 \) was set before estimation. For estimation, we imposed the condition for positive definiteness on the covariance matrix parameters and imposed the stationarity conditions for the AR(2) coefficients. The last row reports the value of the log-likelihood.

5. CONCLUSION

In this paper, we proposed a simple methodology for investigating the correlation between permanent and transitory shocks for unidentified UC models. Although one cannot estimate the correlation in this case, our methodology can be used to obtain an upper bound for the correlation. We applied our methodology to U.S. and U.K. real GDP data. It was found that the upper bounds of the correlations are negative for both countries. This implies that for these two countries, permanent and transitory shocks are strongly negatively correlated.

Our results raise questions about the conventional identification scheme for UC models, which involves setting the correlation parameter to zero. As argued by MNZ in the context of U.S. GDP, imposing such a restriction distorts the estimates of trend and cycle from UC models. Our results confirm this for the case of U.K. GDP. We also showed that the UC model with a stationary AR(2) cycle process is not supported by U.K. real GDP data.
Note: These figures represent the cycle estimates from the UC models estimated under the following restrictions on $\theta_1$: (a) $\theta_1 = 0$; (b) $\theta_1 = 0.5$; and (c) $\theta_1 = -0.5$.

Figure 3. Percentage deviation from trend of U.S. real GDP

Figure 4. Percentage deviation from trend of U.K. real GDP

Note: These figures represent the cycle estimates from the UC models estimated under the following restrictions on $\theta_1$: (a) $\theta_1 = 0.16$; (b) $\theta_2 = 0.22$; (c) $\theta_1 = 0$; and (d) $\theta_1 = -0.5$. 
Appendix

A: Derivation of Equation (6)
Here, we briefly argue how to derive the solutions given in Eq. (6).

Note that we can rewrite (5) as

\[
\begin{bmatrix}
\gamma_0 \\
\gamma_1 \\
\gamma_2
\end{bmatrix} =
\begin{bmatrix}
1 + \phi_1^2 + \phi_2^2 & 2(1 - \theta_1 + \theta_1^2) & 2[1 + \phi_1 + \theta_1(\phi_2 - \phi_1)] \\
\phi_1\phi_2 - \phi_1 & -(1 - \phi_1)^2 & [\phi_2 - \phi_1 - 1 - \theta_1(\phi_2 - \phi_1 - 1)] \\
-\phi_2 & -\theta_1 & -(\theta_1 + \phi_2)
\end{bmatrix}
\begin{bmatrix}
\sigma_\eta^2 \\
\sigma_\epsilon^2 \\
\sigma_\eta\epsilon
\end{bmatrix}.
\]

We can show that the 3 by 3 matrix on the right hand side is non-singular if \(\phi_1 + \phi_2 \neq 1\), \(\theta_1 \neq 1\), and \(\theta_1(\theta_1 + \phi_1) \neq \phi_2\) (and we assume it). Then we can uniquely solve the equation for \(\sigma_\eta^2, \sigma_\epsilon^2, \sigma_\eta\epsilon\) as in (6).

B: State space representation of the UC–ARMA(2, 1) model
We adopt the following state space representation of the UC–ARMA(2, 1) model for estimation of the model parameters and the cycle:

(Observation equation)

\[ y_t = \begin{bmatrix} 1 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} \tau_t \\ c_t \\ c_{t-1} \\ \epsilon_t \end{bmatrix}, \]

(State equation)

\[
\begin{bmatrix}
\tau_t \\
c_t \\
c_{t-1} \\
\epsilon_t
\end{bmatrix} = \begin{bmatrix} \mu \\
0 \\
0 \\
0
\end{bmatrix} + \begin{bmatrix} 1 & 0 & 0 & 0 \\
0 & \phi_1 & \phi_2 & \theta_1 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0
\end{bmatrix} \begin{bmatrix}
\tau_{t-1} \\
c_{t-1} \\
c_{t-2} \\
\epsilon_{t-1}
\end{bmatrix} + \begin{bmatrix}
1 & 0 \\
0 & 1 \\
0 & 0 \\
0 & 1
\end{bmatrix} \begin{bmatrix}
\eta_t \\
\epsilon_t
\end{bmatrix},
\]

for \(t = 1, \ldots, T\) with \(E(\eta_t) = E(\epsilon_t) = 0\), \(\text{var}(\eta_t) = \sigma_\eta^2\), \(\text{var}(\epsilon_t) = \sigma_\epsilon^2\), and \(\text{cov}(\eta_t, \epsilon_s) = \rho\sigma_\eta\sigma_\epsilon\) if \(t = s\) and 0 otherwise. We set the initial conditions, namely, the mean vector and covariance matrix of \((\tau_1, c_1, c_0, \epsilon_1)'\), for starting the Kalman filter recursion, as the stationary mean vector and covariance matrix of \((c_t, c_{t-1}, \epsilon_t)'\) for \((c_1, c_0, \epsilon_1)'\), and \(E(\tau_1) = y_1\) and \(\text{var}(\tau_1) = 10^7\) for \(\tau_1\). The covariances between \(\tau_1\) and \((c_1, c_0, \epsilon_1)'\) are set to zero.

If our objective is only to estimate parameters, it is more convenient to use the following state space representation of the first difference of \(y_t\):
(Observation equation)

\[
\Delta y_t = \begin{bmatrix} 1 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} \Delta \tau_t \\ \Delta c_t \\ \Delta c_{t-1} \\ \varepsilon_t \\ \varepsilon_{t-1} \end{bmatrix},
\]

(State equation)

\[
\begin{bmatrix} \Delta \tau_t \\ \Delta c_t \\ \Delta c_{t-1} \\ \varepsilon_t \\ \varepsilon_{t-1} \end{bmatrix} = \begin{bmatrix} \mu \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & \phi_1 & \phi_2 & \theta_1 - 1 & \theta_1 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \Delta \tau_{t-1} \\ \Delta c_{t-1} \\ \Delta c_{t-2} \\ \varepsilon_{t-1} \\ \varepsilon_{t-2} \end{bmatrix} + \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \begin{bmatrix} \eta_t \\ \varepsilon_t \end{bmatrix}.
\]

This is because then all state variables are stationary and we can avoid the problem of initialization. The same technique can be used for higher order UC-ARMA models. See Durbin and Koopman (2001) for more details of state space models.
